## ***5. General Discussion on CANDU Fuel Management***

### **5.1 General Description**

- ♦ **Refuelling operations in CANDU reactors are carried out with the reactor at power.**
- ♦ **This feature makes the in-core fuel management substantially different from fuel management for reactors which must be refuelled while shut down.**

## ***5.1 General Description***

- ♦ **The CANDU on-power refuelling capability also means that long-term reactivity control can be achieved by an appropriate rate of fuel replacement.**
- ♦ **Therefore, excess core-reactivity requirements are very small:**
- ♦ **Current CANDU reactors use natural-uranium fuel, and the lattice has much smaller excess reactivity than enriched-fuel lattices**
- ♦ **The CANDU fuel bundle (~50-cm long and containing ~19 kg of uranium) allows adding fuel in small increments** (cont'd)

## ***5.1 General Description***

- ♦ **For continuous or short-term reactivity control, a capability of only a few milli-k is necessary; this is provided in the light-water zone-control compartments**
- ♦ **Other than in the initial core, there are no large batches of fresh fuel,**
- ♦ **and therefore no need for burnable poison or large amounts of moderator poison to compensate for high excess reactivity;**
- ♦ **in the initial core, when all fuel is fresh, only ~2-3 ppm of moderator boron are required**

---

## ***5.1 General Description***

- ♦ **These factors lead to excellent neutron economy and low fuelling costs.**
- ♦ **Also, since power production is not interrupted for refuelling, it is not necessary to tailor the refuelling schedule to the utility's system load requirements.**

## ***5.1 General Description***

- ♦ **To refuel a channel, a pair of fuelling machines latch onto the ends of the channel.**
- ♦ **A number of fresh fuel bundles are inserted into the channel by the machine at one end,**
- ♦ **and an equal number of irradiated fuel bundles are discharged into the machine at the other end of the channel.**
- ♦ **[Note: the fuelling machines are very high-tech machines, they must “break into” the heat-transport system at full pressure, with no (or small) leaks]**

## ***5.1 General Description***

- ♦ **For symmetry, the refuelling direction is opposite for neighbour channels.**
- ♦ **In the CANDU-6 reactor, the refuelling direction is the same as that of coolant flow in the channel.**
- ♦ **In some other CANDU reactors (e.g., Bruce) the refuelling direction was designed to be against coolant flow.**
- ♦ **Refuelling with flow presents advantages in some kinds of hypothetical loss-of-coolant accidents.**

## ***5.1 General Description***

- ♦ **Figure 5.1 illustrates the 8-bundle-shift scheme,**
- ♦ **where the eight bundles near the outlet end of the channel are discharged,**
- ♦ **and the four bundles previously nearest the inlet end are shifted nearest to the outlet end.**
- ♦ **Thus, the four low-power bundles are in-core for two cycles, and**
- ♦ **the high-power bundles are in-core for only one cycle.**

## ***5.1 General Description***

- ♦ **Several refuelling operations are normally carried out daily,**
- ♦ **so that refuelling is almost continuous.**
  
- ♦ **CANDU reactors offer extreme flexibility in refuelling schemes:**
- ♦ **The refuelling rate (or frequency) can be different in different regions of the core,**
- ♦ **and in the limit can in principle vary from channel to channel.** (cont'd)

## *5.1 General Description*

- ♦ **By using different refuelling rates in different regions, the long-term radial power distribution can be shaped and controlled.**
- ♦ **The axial refuelling scheme is not fixed; it can be changed at will. It can be different for different channels.**
- ♦ **It need not even be the same always for a given channel: it can vary at every visit of the channel. Eight-, 4-, or 10-bundle-shift refuelling schemes have been used.**

---

## ***5.1 General Description***

- ♦ **A channel can be refuelled without delay if failed fuel exists or is suspected.**
- ♦ **In such a case, when there is concern that replacing all fuel bundles in the channel would drive its power too high, some depleted-uranium bundles can be mixed with standard bundles to limit the power.**
- ♦ **This is made possible by the subdivision of the fuel in a CANDU channel into short bundles.**

---

## ***5.2 Overall Objectives***

- ♦ **The primary objective of fuel management is to determine fuel-loading and fuel-replacement strategies**
- ♦ **to operate the reactor in a safe and reliable fashion while keeping the total unit energy cost low.**

## ***5.2 Overall Objectives***

- ♦ **Within this context, the specific objectives of CANDU fuel management are as follows:**
- ♦ **The reactor must be kept critical and at full power. On-power fuelling is the primary means of providing reactivity. If the fuelling rate is inadequate, the reactor eventually has to be derated.**
- ♦ **The core power distribution must be controlled to satisfy safety and operational limits on fuel power.**

## ***5.2 Overall Objectives***

- ♦ **The fuel burnup is to be maximized within the operational constraints, to minimize the fuelling cost**
- ♦ **Fuel defects are to be avoided. This minimizes replacement fuel costs and radiological occupational hazards.**
- ♦ **The fuel-handling capability must be optimized. This minimizes capital, operating and maintenance costs.**

## ***5.3 Periods During Operating Life of Reactor***

- ♦ **From the point of view of fuel management, the operating life of a CANDU reactor can be separated into three periods.**
- ♦ **The first two are short, transitional periods,**
- ♦ **while the third, the “equilibrium core”, represents about 95% of the lifetime of the reactor.**

## ***From First Criticality to Onset of Refuelling***

- ♦ The first period is from first criticality until onset of refuelling.
- ♦ It is of limited duration, about 100 to 150 full-power days (FPD) long.
- ♦ The reactor is initially loaded with natural-uranium fuel everywhere,
- ♦ except for a small number of depleted-fuel bundles at specific core locations, designed to help flatten the power distribution.

---

## *From First Criticality to Onset of Refuelling*

- ♦ Consequently, at this time, for the only time in the life of the reactor, there is a fair amount of excess reactivity.
- ♦ This is compensated by adding boron poison to the moderator.

## *From First Criticality to Onset of Refuelling*

- ♦ At about 40-50 FPD of reactor operation, the core reaches its “plutonium peak”
- ♦ At this time the core reactivity is highest,
- ♦ due to the production of plutonium by neutron capture in  $^{238}\text{U}$ , and the as-yet relatively small  $^{235}\text{U}$  depletion and fission-product concentration.
- ♦ Following the plutonium peak, the plutonium production can no longer compensate for the buildup of fission products, and the excess core reactivity decreases.

## *Onset of Refuelling and Transition to Equilibrium Core*

- ♦ When the excess core reactivity has fallen to a small value, refuelling begins in order to maintain the reactor critical.
- ♦ During the transitional period which follows, the reactor gradually approaches the final or “equilibrium” state.
- ♦ The average refuelling rate and in-core burnup are transitional but start to converge towards steady values.

## *Equilibrium Core*

- ♦ Approximately 400 to 500 FPD after initial start-up, a CANDU reactor has reached a state which may be termed an “equilibrium core”.
- ♦ The overall refuelling rate, the in-core average burnup, and the burnup of the discharged fuel
- ♦ have become essentially steady with time.

## *Equilibrium Core*

- ♦ The global flux and power distributions can be considered as having attained an equilibrium,
- ♦ “time-average” shape
- ♦ The refuelling of individual channels leads to local “refuelling ripples” about the time-average shape.
- ♦ These ripples are due to the various instantaneous values of fuel burnup in the different channels,
- ♦ which are the result at any given instant of the specific sequence of channels refuelled.

## *Equilibrium Core*

- ♦ With some refuelling operations taking place essentially every day,
- ♦ the equilibrium core contains, at all times, fuel with a range of burnups, from 0 to some average exit-burnup value.
- ♦ The exit-burnup value is the long-term burnup of fuel at discharge from the reactor.
- ♦ The average in-core burnup at any time is approximately one half of the exit burnup.

## ***5.4 Infinite-Lattice Multiplication Constant***

- ♦ The infinite-lattice multiplication constant  $k_{\text{inf}}$  is a measure of the multiplicative properties of the lattice,
- ♦ in the absence of leakage from the lattice cell.
- ♦ The  $k_{\text{inf}}$  is provided by a cell code, such as POWDERPUFS-V, and applies to the “ideal” situation of an infinite array of identical cells.

## ***5.4 Infinite-Lattice Multiplication Constant***

- ♦ Fig. 5.2 shows the  $k_{inf}$  as a function of irradiation for the standard CANDU 6 lattice fuelled with natural uranium.
- ♦ The figure shows that the lattice is  $\sim 80$  milli-k supercritical for fresh fuel (i.e., at zero irradiation).
- ♦ Important note: the figure shows  $k_{inf}$ , the reactivity for the “infinite”, bare lattice. An estimate of the  $k_{eff}$  for a finite reactor can be obtained by subtracting about 50 milli-k (30 milli-k for leakage and 20 milli-k for in-core devices - zone controllers and adjusters)

## ***5.4 Infinite-Lattice Multiplication Constant***

- ♦ The reactivity increases at first with increasing irradiation, reaching a maximum at approximately 0.4-0.5 n/kb, a phenomenon due to the production of plutonium from neutron absorption in  $^{238}\text{U}$ .
- ♦ This reactivity maximum is consequently known as the plutonium peak.

## ***5.4 Infinite-Lattice Multiplication Constant***

- ♦ **Beyond the plutonium peak, the reactivity starts to decrease with increasing irradiation.**
- ♦ **This is due to the continuing depletion of  $^{235}\text{U}$  and the increasing fission-product load.**
- ♦ **From Fig. 5.2,  $k_{\text{inf}}$  reaches a value of 1.050 (which means an approximately critical reactor) at an irradiation of about 0.9 n/kb.**

## ***5.4 Infinite-Lattice Multiplication Constant***

- ♦ This means the reactor is critical when the *average in-core* irradiation is about 0.9 n/kb.
- ♦ About twice this value, i.e., ~1.8 n/kb, marks a natural exit irradiation, the point at which the fuel can be targeted for removal from the core,
- ♦ since at higher irradiations the average lattice becomes increasingly subcritical, i.e., an increasing net absorber of neutrons.

## *5.4 Infinite-Lattice Multiplication Constant*

- ♦ Thus, channels containing fuel approaching or exceeding an irradiation of  $\sim 1.7\text{-}1.8$  n/kb become good candidates for refuelling. (This is a very general statement, which is made more specific in a later section.)
- ♦ The corresponding exit burnup is in the range 7,300-7,500 MWd/Mg(U) [175-180 MW.h/kg(U)] - however, note that this can vary with lattice conditions, especially the moderator purity.

## ***5.4 Infinite-Lattice Multiplication Constant***

- ♦ It is instructive to examine also the infinite-lattice multiplication constant for the depleted-uranium lattice.
- ♦ This is shown in Fig. 5.3 for depleted uranium with an initial fissile content of 0.52 atom % (as opposed to 0.72 atom % for natural uranium).
- ♦ Note that the plutonium peak is even more pronounced for depleted uranium.
- ♦ This is easily explained by the fact that the role of  $^{238}\text{U}$  conversion to plutonium is relatively greater when the smaller  $^{235}\text{U}$  content.

## ***5.4 Infinite-Lattice Multiplication Constant***

- ♦ **Note also, however, that the depleted-uranium lattice is subcritical at all irradiations,**
- ♦ **i.e. it is always a neutron absorber.**
- ♦ **This explains the use of depleted fuel to reduce excess reactivity, and also flatten the flux distribution, in the initial core.**
- ♦ **Depleted fuel is also occasionally used to reduce the power ripple on refuelling.**
